AB Fungi rely on the enzyme chitin synthase (CS) to produce chitin (poly-N-acetylglucosamine, GlcNAc), an essential cell wall component involved in cellular reprodn. The enzyme polymerizes long chains of chitin utilizing an activated donor substrate, UDP-GlcNAc. The native structure of chitin has a screw-axis in which each GlcNAc monomer is rotated 180 degrees relative to the adjacent GlcNAc in the chain. Similar to other **processive glycosyltransferases** (cellulose and hyaluronan synthases), CS is membrane bound, few structural data exist, and little is known about its mechanism and how the enzyme accounts for the twist in the final structure. The weak affinity CS has for UDP-GlcNAc has precluded successful substrate-based inhibitors. We hope to exploit and demonstrate a previously proposed mechanism of action, in which two units of GlcNAc are added simultaneously or sequentially by two active sites. Preliminary results of a series of dimeric inhibitors will be presented.

AB A review. Cellulose synthase genes (CesAs) encode a broad range of **processive glycosyltransferases** that synthesize (1.fwdarw.4).beta.-D-glycosyl units. The proteins predicted to be encoded by these genes contain up to eight membrane-spanning domains and four "U-motifs" with conserved aspartate residues and a QxxRW motif that are essential for substrate binding and catalysis. In higher plants, the domain structure includes two plant-specific regions, one that is relatively conserved and a second, so-called "hypervariable region" (HVR). Anal. of the phylogenetic relationships among members of the CesA multi-gene families from two grass species, Oryza sativa and Zea mays, with Arabidopsis thaliana and other dicotyledonous species reveals that the CesA genes cluster into several distinct sub-classes. Whereas some sub-classes are populated by CesAs from all species, two sub-classes are populated solely by CesAs from grass species. The sub-class identity is primarily defined by the HVR, and the sequence in this region does not vary substantially among members of the same sub-class. Hence, we suggest that the region is more aptly termed a "class-specific region" (CSR). Several motifs contg. cysteine, basic, acidic and arom. residues indicate

that the CSR may function in substrate binding specificity and catalysis. Similar motifs are conserved in bacterial cellulose synthases, the Dictyostelium discoideum cellulose synthase, and other **processive glycosyltransferases** involved in the synthesis of non-cellulosic polymers with (1.fwdarw.4).beta.-linked backbones, including chitin, heparan, and hyaluronan. These analyses re-open the question whether all the CesA genes encode cellulose synthases or whether some of the sub-class members may encode other non-cellulosic (1.fwdarw.4).beta.-glycan synthases in plants. For example, the mixed-linkage (1.fwdarw.3)(1.fwdarw.4).beta.-D-glucan synthase is found specifically in grasses and possesses many features more similar to those of cellulose synthase than to those of other .beta.-linked crosslinking glycans. In this respect, the enzymic properties of the mixed-linkage .beta.-glucan synthases not only provide special insight into the mechanisms of (1.fwdarw.4).beta.-glycan synthesis but may also uncover the genes that encode the synthases themselves.

AB SUMMARY: Cellulose, an aggregate of unbranched polymers of beta-1,4-linked glucose residues, is the major component of wood and thus paper, and is synthesized by plants, most algae, some bacteria and fungi, and even some animals. The genes that synthesize cellulose in higher plants differ greatly from the well-characterized genes found in Acetobacter and Agrobacterium sp. More correctly designated as 'cellulose synthase catalytic subunits', plant cellulose synthase (CesA) proteins are integral membrane proteins, approximately 1,000 amino acids in length. The sequences for more than 20 full-length CesA genes are available, and they show high similarity to one another across the entire length of the encoded protein, except for two small regions of variability. There are a number of highly conserved residues, including several motifs shown to be necessary for **processive glycosyltransferase** activity.
No crystal structure is known for cellulose synthase proteins, and the exact enzymatic mechanism is unknown. There are a number of mutations in cellulose synthase genes in the model organism Arabidopsis thaliana. Some of these mutants show altered morphology due to the lack of a properly developed primary or secondary cell wall. Others show resistance to well-characterized cellulose biosynthesis inhibitors.

AB The effort to sequence the entire Arabidopsis genome has proven to be a treasure trove for plant mol. biologists and cell wall researchers. A large superfamily of cellulose synthase (CesA) and cellulose synthase-like (Csl) genes has been identified in Arabidopsis, consisting of at least six subfamilies and over forty different genes. Homologs of many of these genes have been found in a wide variety of plant species, from mosses to trees. Sequence anal. indicates that these genes have conserved protein domains found in **processive glycosyltransferases**. Our lab. is taking a reverse genetic approach to detg. the function of several of these families of putative glycosyltransferases. I will discuss our progress in answering four important questions: where and when are these genes expressed, what is their enzymic function, and what is their importance in the biosynthesis of the plant cell wall.

AB We have analyzed the globular region of cellulose synthase from Acetobacter xylinum by site-directed mutagenesis and motif anal., and obtained a structural model of this region using the genetic algorithm. Mutagenesis data confirmed that the conserved residues are essential for enzyme activity. The predicted structure of the catalytic region reveals the presence of a central elongated cavity between the conserved aspartic acid residues. The dimension of the cavity suggests that it can accommodate two UDP-glucose residues. The QXXRW motif is predicted to be involved in the binding of the growing glucan chain and residues in this motif are shown to be present in a region close to the central cavity. A similar structure was also obtained for the globular region of cellulose synthase from cotton. Based on our anal. of the globular region of cellulose synthase we have proposed a general model for the structure and action of **processive glycosyltransferases**.

AB The title enzymes and their use are disclosed. Thus, the ypfP gene of B. subtilis and of S. aureus were expressed in Escherichia coli. Both enzymes utilized UDP-glucose, and catalyzed addn. of up to 4 glucosyl moieties in .beta.(1.fwdarw.6) linkage to the substrates. The Bacillus enzyme used diacylglycerol, monoglucosyl diacylglycerol, diglucosyl diacylglycerol and alkyl-.alpha./.beta.-D-glucopyranosides as acceptor. The Staphylococcus enzyme could also use sterols and sterylglucosids as acceptors. Two novel phosphoglycolipids were identified.

AB Lipochitin oligosaccharides are organogenesis-inducing signal mols. produced by rhizobia to establish the formation of nitrogen-fixing root nodules in leguminous plants. Chitin oligosaccharide biosynthesis by the Mesorhizobium loti nodulation protein NodC was studied in vitro using membrane fractions of an Escherichia coli strain expressing the cloned M. loti nodC gene. The results indicate that prenylpyrophosphate-linked intermediates are not involved in the chitin oligosaccharide synthesis pathway. It was obsd. that, in addn. to N-acetylglucosamine (GlcNAc) from UDP-GlcNAc, NodC also directly incorporates free GlcNAc into chitin oligosaccharides. Further anal. showed that free GlcNAc is used as a primer that is elongated at the nonreducing terminus. The synthetic glycoside p-nitrophenyl-.beta.-N-acetylglucosaminide (pNPGlcNAc) has a free hydroxyl group at C4 but not at C1 and could also be used as an acceptor by NodC, confirming that chain elongation by NodC takes place at the nonreducing-terminal residue. The use of artificial glycosyl acceptors such as pNPGlcNAc has not previously been described for a **processive glycosyltransferase**. Using this method, it was also shown that also the DG42-directed chitin oligosaccharide synthase

activity, present in exts. of zebrafish embryos, is able to initiate chitin oligosaccharide synthesis on pNPGlcNAc. Consequently, chain elongation in chitin oligosaccharide synthesis by M. loti NodC and zebrafish DG42 occurs by the transfer of GlcNAc residues from UDP-GlcNAc to O4 of the nonreducing-terminal residue, in contrast to earlier models on the mechanism of **processive** .beta.-glycosyltransferase reactions.

AB The "parallel-up" packing in cellulose I.alpha. and I.beta. unit cells was exptl. demonstrated by a combination of direct-staining the reducing ends of cellulose chains and microdiffraction-tilting electron crystallog. anal. Microdiffraction investigation of nascent bacterial cellulose microfibrils showed that the reducing end of the growing cellulose chains points away from the bacterium, and this provides direct evidence that polymn. by the cellulose synthase takes place at the nonreducing end of the growing cellulose chains. This mechanism is likely to be valid also for a no. of **processive glycosyltransferases** such as chitin synthases, hyaluronan synthases, and proteins involved in the synthesis of nodulation factor backbones.

AB The title enzymes and their use are disclosed. Thus, the ypfP gene of B. subtilis and of S. aureus were expressed in Escherichia coli. Both enzymes utilized UDP-glucose, and catalyzed addn. of up to 4 glucosyl moieties in .beta.(1.fwdarw.6) linkage to the substrates. The Bacillus enzyme used **diacylglycerol**, monoglucosyl **diacylglycerol**, diglucosyl **diacylglycerol** and alkyl-.alpha./.beta.-D-glucopyranosides as acceptor. The Staphylococcus enzyme could also use sterols and sterylglucosids as acceptors. Two novel phosphoglycolipids were identified.
